This version: 15 February 2022

*Preliminary version, please do not circulate without the authors' permission.*

Using a unique dataset of 500,000 Chinese firms that use a QR-code-based mobile payment system, we find that (i) the creation of a digital payment footprint allows firms to access credit provided by the same big tech company; (ii) transaction data generated via QR code generate spillover effects on access to bank credit; and (iii) there are positive effects of access to big tech credit on sales, including during the Covid-19 shock. The findings suggest that access to innovative payment methods help micro firms build up credit history and the use of big tech credit can ease access to bank credit.

JEL classification: D22, G31, R30.

Keywords: big tech, big data, QR code, banks, asymmetric information, financial inclusion, credit markets.

## 1. Introduction

The presence of information asymmetries between small firms and credit intermediaries is a serious problem that may reduce financing of good investment opportunities and the development of promising entrepreneurs' projects (Petersen and Rajan, 1994; Berger and Udell, 1995, 2006). Possible solutions to mitigate this problem for small enterprises are posting collateral or relying on credit history (techniques often referred to as transaction-based lending) or building close and long-term relationships with specific lenders (often referred to as relationship lending). Big data and machine learning, however, have provided a new solution, allowing large technology firms (also referred to as big techs) to use credit-scoring techniques to provide lending for clients operating in their business platforms (BIS, 2019).

This paper gauges the example of Ant Group, which started providing payment services through QR codes, thus enabling off-line merchants access to digital payment services, and uses the information collected through these services to decide on credit provision to merchants. We find that the use of QR codes for payment services allows such off-line merchants to not only gain access to credit from the big tech company but also (by being included in the credit registry after having received big tech loans) access to unsecured bank credit. We also document positive real effects of the use of big tech credit, including during the Covid-19 pandemic, where recovery in transactions was 20% more pronounced for users of big tech and non-users.

Theory and evidence have provided contrasting evidence on the role of new providers of financial services, such as fintech and big tech companies as substitutes or complements for incumbent banks. Our findings point to the potential of big tech companies to provide credit services to previously unbanked small firms, but also the positive spillover effects that the use of big tech loans can have for access to bank credit.

Big techs are large companies that operate platforms enabling direct interaction among a large number of users over a range of businesses, including e-commerce, social media, internet search, mobile phone hardware and software, ride hailing and telecommunications (Frost et al 2019; Stulz, 2019). Increasingly, big techs have become substantial players in payments in several advanced and emerging market economies (FSB, 2019a; 2019b). They account for 94% of mobile payments in China

(Carstens et al, 2021). Globally, big tech credit grew by 40% in 2020 alone, to a total of over \$700 billion. In some jurisdictions big techs have participated in government credit schemes during the Covid-19 pandemic period (Cornelli et al, 2021).

The use of Quick Response (QR) codes, as used by Ant Group, can have positive effects for financial inclusion beyond the simple efficient processing of transaction payments. Small businesses not equipped with POS machines are now able to collect payment through a simple QR Code, that could be easily printed by themselves. A QR scan code system allows small vendors to improve the processing of payments and provide, at the same time, relevant information to payment companies that operate the platforms. For example, in China firms that are active in the e-commerce platform (i.e., online merchants operating on Taobao and Tmall, two Alibaba e-commerce platforms) are integrated into the big tech's platform ecosystem. The big tech is thus able to collect a large number of information not only on clients' payment transactions but also on their input-output production chain and their clients network. Big tech companies can use these data and make a very precise assessment of firms' behaviors and characteristics. Importantly, the collection of data is possible also for offline merchants (e.g., a shop or a restaurant) that do not trade on the e-commerce platform.

In addition to more effective payment services, the use of QR payment services generates a vast amount of data that can be used to know better risk profile of customers and provide them with other financial services. For example, the application of machine learning techniques on big data is widely used for credit scoring and this allows mitigate asymmetric information problems between lenders and borrowers. As mentioned above, payment data are collected not only for firms that operate on the e-commerce platform (online firms) and are perfectly integrated in the big tech ecosystem, but also for firms that operate on other more traditional business channels (offline). Payment data are typically merged with other non-traditional data derived from the use of apps or social media.

This paper explores whether (i) the use of QR code in payments allows firms to have access to big tech credit, (ii) access/use of big tech credit allows firms to have access to more traditional bank credit, and (iii) there are real effects of the use of QR code in payment and the subsequent provision of credit on firms' business volume.

To answer these questions, we use a unique dataset that compares the characteristics of loans provided by a MYbank, one of the brands under Ant Group (an important big tech company in China) with loans supplied by traditional financial institutions. In particular, we analyse a random sample of around 500,000 Chinese firms that received credit from a big tech company and/or traditional financial institutions in the period 2017:01-2020:07. We consider the period 2017:01-2019:12 for our baseline results and use the Covid pandemic period (2020:01-2020:06) for a specific test on the real effects of the use of big tech credit as a cushion against the shock. We have access to detailed information on credit supplied by MYBank and firm characteristics on a monthly frequency.<sup>1</sup> In particular, we have access to credit data (quantity and price), and specific information used to model firms' creditworthiness, such as vendor transaction volumes and their network score. The latter measures users' centrality in the network and is based on a firm's payments history and social interactions of the entrepreneur in the Alipay ecosystem.

We find that the creation of a digital payment footprint allows firms to access other financial services and products offered by big techs. We also find that the use of big tech financial services and transaction data generated via QR code generates spillover effects on bank credit. Specifically, the inclusion of big tech credit exposure in the credit registry act as a signalling device and allows SMEs to access also more traditional banking services. Further, the use of credit lines offered to the firms has positive effects on firms' business volume. These effects are quantitatively small in normal times, reflecting the use of credit lines mainly for liquidity management, not to expand the business, but significantly larger during the Covid-19 period, when credit lines are used to insulate the effects of an unexpected shock.

We contribute mostly to four broad strands of literature. First, we provide new supportive evidence on the real effect of fintech credit (especially for big tech credit) and the way it can contribute to financial inclusion (BIS, 2019). Barrot and Nanda (2020) find strong direct effect of Quick pay, a reform that permanently accelerated payments to small business contractors, on the employment growth at the firm level. Using data from Alibaba's online retail platform, Hau et al. (2021) show that fintech credit approval and credit use boost a vendor's sales and transaction growth. Suri et

---

<sup>1</sup> All the data remained located at the Ant Group headquarters and the regression analysis was conducted onsite by employees of MYbank, without the need to export the raw data.

al. (2021) studies the Kenyan case and find that fintech credit can improve households' resilience: households are 6.3 percentage points less likely to forego expenses due to negative shocks. Similarly, Ji et al. (2021) finds that individuals' consumption significantly increases after being extended fintech consumer credit. Our paper contributes by complementing these results and finding that use of QR payments increases the probability of credit access/use for small and micro businesses and that this has positive effects on firms' business volumes. Unlike previous studies, our sample of firms contains not only firms operating on the e-commerce platforms (online firms) but also those that use more traditional business channels (offline firms).

Second, our paper is related to the literature that studies the interaction between fintech and traditional banking. Tang (2019) shows for the US that P2P lending is a substitute for bank lending in terms of serving infra-marginal bank borrowers yet complements bank lending with respect to small loans, while Cornaggia et al. (2018) find that high-risk fintech loans tend to substitute bank loans, while low-risk loans complement them and tend to expand the overall mass of credit provided to the economy. Our paper aims to show if big tech credit rather than fintech credit is a complement or a substitute to bank loans. Chava et al. (2021) find that borrower of marketplace lenders (MPL) reduce their traditional credit card balances after MPL origination, which increase their credit scores and ultimately enables additional lending from banks, thus higher aggregate indebtedness and ultimately higher default rates. Di Maggio and Yao (2021) show that fintech lender in the US acquire market share by lending first to higher-risk borrowers and then to safer borrowers and rely mainly on hard information to make credit decisions. In our paper, we show that the use of big tech financial services and transaction data generated via QR code generates spillover effects on bank credit; the inclusion of big tech loans in the credit registry allows SMEs to be better screened/monitored by banks. With this we also connect to a small literature focusing specifically on spillover effects from one segment of the financial system to another; Agarwal et al. (2021), for example, examine the impact of a large-scale microcredit expansion program in Rwanda on financial access and show that a sizable share of first-time borrowers switched to banks, which cream-skim less risky borrowers and grant them larger, cheaper, and longer maturity loans.

Third, we contribute to the empirical literature that studies asymmetric information problems in credit markets. In this stream of the literature, collateral plays a key role in

mitigating the financial constraints for the development of economic activity (Stiglitz and Weiss, 1981; Besanko and Thakor, 1987; Cerqueiro et al, 2016). Schmalz et al (2016) find that an increase in collateral value (proxied by house price) leads to a higher probability of becoming an entrepreneur. Our paper investigates how the use of massive data by large technology firms to assess firms' creditworthiness could reduce the need of collateral in solving asymmetric information problems. Another important way to mitigate asymmetric information problems is the creation of a long-term credit relationship between a bank and a firm (Berger and Udell, 1992; Petersen and Rajan, 1994). Several studies have shown that banking relationships continue to smooth credit supply to firms when banks themselves face external liquidity shocks in a downturn (Bolton et al (2016); Beck et al (2018)). Our paper analyses the impact of big tech lending (that is of different nature with respect to relationship lending) in case of the Covid-19 pandemic shock in order to evaluate its capacity to smooth the negative effects on firms' activity.

Fourth, the paper contributes to the recent literature that looks at the informational content of digital soft information and credit performance. Dorfleitner et al. (2016) study the relationship between soft factors in P2P loan applications and financing and default outcomes. Using data on the two leading European P2P lending platforms, Smava and Auxmoney, they find that soft factors influence the funding probability but not the default probability. Jagtiani and Lemieux (2018a) find that the rating grades assigned on the basis of alternative data perform well in predicting loan performance over the two years after origination. The use of alternative data has allowed some borrowers who would have been classified as subprime by traditional criteria to be slotted into "better" loan grades, enabling them to benefit from lower priced credit. In addition, for the same risk of default, consumers pay smaller spreads on loans from LendingClub than from credit card borrowing. Berg et al. (2020) show that digital footprints are a good predictor of the default rate. Analysis of simple, easily accessible variables from digital footprints is equal to or better than the information from credit bureau scores. Iyer et al. (2016) analyse the performance of new online lending markets that rely on nonexpert individuals to screen their peers' creditworthiness. They find that these peer lenders predict an individual's likelihood of defaulting on a loan with 45% greater accuracy than the borrower's exact credit score (unobserved by the lenders, who only see a credit category). The results show how aggregating over the views of

peers and leveraging nonstandard information can enhance lending efficiency. Gambacorta et al. (2019) find that the credit scoring models based on machine learning and non-traditional data are better able to predict losses and defaults than traditional models in the presence of a negative shock to the aggregate credit supply. Huang et al. (2020) shows that fintech risk management could benefit small business relatively more. Our paper provides new evidence showing that use of transaction data generated via QR code payments improves big tech credit scoring techniques and that this allows SMEs to be better screened/monitored.

The rest of the paper is organised as follows. Section 2 presents the data and describes some stylised facts. Section 3 explains our empirical strategy and how we tackle identification issues. Section 4 presents the main results and robustness tests. The last section summarises the main conclusions. The Appendix reports supplementary material.

## **2. Data and stylized facts**

The empirical analysis in this paper focuses on Chinese micro and small enterprises that obtained credit from Ant Group.<sup>2</sup> For these firms, we can also observe their credit history and we can distinguish between collateralised and unsecured bank credit. All credit by Ant Group is unsecured and is provided by MYbank.

The database is constructed at the firm-month level over the period 2017:01 to 2020:07. The sample includes around 500,000 firms that have been randomly selected from a larger sample of more than 80 million firms that recorded transaction records every month and obtained bank credit since January 2017. We use two different samples in our estimations, one on a monthly basis from 2017 to 2019 and one on a weekly basis from the end of October 2019 to June 2020.

Table 1a presents the summary statistics on our monthly database for normal times (2017:01-2019:12) and is divided into four panels: (i) Credit information; (ii) Firms' characteristics; (iii) Entrepreneurs' characteristics; (iv) Economic and financial

---

<sup>2</sup> The *Alibaba Group* is one of the biggest tech companies in the world. It was publicly listed on the New York Stock Exchange in September 2014 and on the Hong Kong Stock Exchange in November 2019. Alibaba has a market capitalisation of around USD 305 billion USD in NYSE and HKD 2.4 trillion in SEHK as of 28<sup>th</sup> January 2022. *Alipay* is a third-party mobile and online payment platform, established by the Alibaba Group that was subsequently rebranded as *Ant Financial Services Group* in October 2014 and *Ant Group* in June 2020.

conditions. Panel B reports weekly data that focus on the pre-pandemic period (2019.10.1-2020.1.25) and the pandemic period (2020.1.26-2020.6.30). The Appendix includes summary statistics separately for firms that had access to big tech credit, firms that used it and bank borrowers.

For big tech credit, we have more than 9 million firm-month observations. Over the sample period 58.2% of the observations refer to QR Code merchants that had access to big tech credit and 4.8% to merchants who also used it. The use of bank credit is much more limited: less than 1% of the QR Code merchants use bank credit (0.5% use unsecured bank credit and 0.2% use secured bank credit).

Looking only at those firms that use bank credit (i.e., “banked firms”), we find that only 11% of these firms use also big tech credit (Figure 1). Among firms with bank credit, only very few have no access to MYbank credit (only 0.2% of the cases) or have access to but do not use MYbank credit (0.5%). The separation of bank and MYbank client is even more stringent in the case of secured bank credit borrowers, where fewer than 2% also use MYbank credit. Overall, this suggests that among QR Code users traditional bank and MYbank borrowers are predominantly separate groups.

The median credit volume for big tech borrowers is RMB 10,000 (USD 1500), reflecting the micro nature of MYbank credit and the short maturity of the contract. Big tech credit is typically granted for short periods and in the form of a credit line (mainly 1 month; see Figure 2) and then rolled over, as long as the credit approval remains in place. The median bank credit is of RMB 80,773 (USD 12,100); the larger size of the loan also comes with longer loan maturity (1 to 3 years). By contrast, the difference in firm size between big tech and bank credit users is not large. The median monthly transaction volume of firms that use big tech credit is RMB 3,388 (USD 510), while that for firms that use bank credit is RMB 4,485 (USD 705). Interestingly, the median firm that uses big tech credit is less connected in the big tech ecosystem than firms that use bank credit (the network scores - that measures users’ centrality in the ecosystem - are 49 and 54, respectively).<sup>3</sup> There is a positive correlation between firms’ size and access to MYbank credit, as well as between MYbank credit use and bank credit use.

---

<sup>3</sup> The network score is obtained as a rank calculated using a PageRank algorithm. This algorithm was introduced by Larry Page, one of the founders of Google, to evaluate the importance of a particular website page. The calculation is done by means of webgraphs, where webpages are nodes and hyperlinks are edges. Each hyperlink to a page counts as a vote of support for that webpage. In the case of the Ant Group network score, customers and QRcode merchants can be considered as interconnected nodes (webpages) and payment funding flows can be considered as edges (hyperlinks).

Borrowers who access big tech credit are slightly younger (the median age is 34 years) than the owners of firms that use bank credit (36 years). More female entrepreneurs have access to MYbank credit.<sup>4</sup> Despite the larger access to MYbank credit, female entrepreneurs tend to use less MYbank credit and bank credit.

### 3. Empirical strategy

We use duration models to gauge the time period that elapses between when a firm starts to use the QR code for payments and a given event (e.g., access to big tech credit, use of big tech credit or use of bank credit) referring to this time as *QR Code duration*. Duration models are applied in many economic fields, include the modelling of the length of time for a firm to go into default (e.g., Baele et al., 2014) or for individuals to remain unemployed (e.g., Kiefer, 1988).

We estimate a duration model with exponential distribution as a baseline hazard function. The sign of coefficients on the regressors indicate if they contribute to increasing or decreasing the time that elapses between when a firm starts to use the QR code for payments and a given event. In particular, a positive sign of the coefficient indicates that the specific regressor shorten such time, whereas a negative sign of the coefficient indicates that the regressor tend to increase this time. The hazard rate  $h_i(t)$  (probability that a given event happens at time  $t$ ) for firm  $i$  is given by:

$$h_i(t) = \lambda(t) \exp \left( \sum_{j=1}^m (\beta_j x_{ij}) \right) \quad (1)$$

where, independent variables ( $x_{ij}$ ) include firms' financial and business conditions, macroeconomic variables, time and province fixed effects.  $\lambda(t)$  is the baseline hazard function. Different kinds of proportional hazard models may be obtained by making different assumptions about the baseline hazard function. In our paper, we assume that the baseline risk is constant over time, so  $\lambda(t) = \lambda$ , therefore the model is given by:

$$h_i(t) = \lambda \exp \left( \sum_{j=1}^m (\beta_j x_{ij}) \right) \quad (2)$$

Therefore, the probability a given event happens before time  $t$  (where  $t$  is the time that

---

<sup>4</sup> This fact is very interesting because, in general, female entrepreneurs tend to be less financial included when considering traditional banks. In particular, data from the SME Finance Forum indicate that China's 74 million SMEs face a share of financially excluded entrepreneurs of 43 percent, rising to almost 63 percent for women-owned SMEs. See [202008\\_D2E\\_MyBank.pdf \(ifc.org\)](https://www.ifc.org/~/media/202008_D2E_MyBank.pdf).

elapses between a firm starts to use the QR code) is given by:

$$S_i(t) = \int_0^t h_i(t)dt = \int_0^t \lambda \exp\left(\sum_{j=1}^m (\beta_j x_{ij})\right) dt \quad (3)$$

We consider three main events in our paper: (i) the time that elapses between the date a firm starts to use the QR code and the date the firm **gets access to big tech credit**, (ii) the time that elapses between when a firm starts to use the QR code and when the firm starts to **use big tech credit**, and (iii) the time that elapses between when a firm starts to use the QR code and when the firm **obtains a loan from a traditional bank**.

## 4. Results

### 4.1 Does the use of QR code in payment allow firm to have access to big tech credit?

Figure 3 shows a rapid increase in the likelihood of gaining access to big tech credit the longer a firm uses the QR code in payments. We start our analysis with the duration model that describes the amount of time that elapses between when a firm starts to use the QR code and when she receives the offer of a credit line from MYbank. The analysis is based on the Kaplan-Meier survival estimate, with the Y-axis reporting the probability of having access to big tech credit and the X-axis reporting *QR Code Duration*.<sup>5</sup> The figure shows that after one year from starting use QR code payments, the probability to have access to a big tech credit line is almost 60 per cent. This probability increases to 80 per cent after two years.

The first column of Table 2 reports the regression results of the duration model with time-invariant borrower characteristics (gender, age, house property, distance to bank branch), together with transaction volumes and network score. The probability to get big tech access increases by 64% if transaction volume increases by 10% at a specific point of time.<sup>6</sup> The amount of time that it takes between when a firm starts to use the QR code and when she receives the offer of a credit line from the big tech is faster for

---

<sup>5</sup> For ease of representation, we show our results in graphical format computing the Kaplan and Meier (1958) estimators that indicate the probability that a given event occurs before  $t$ . The graphs report a non-parametric estimate of the failure probability (1-survival probability) as a function of time  $t$ .

<sup>6</sup> The coefficient is 0.0494. This means that if transaction volume increases by 10%, the probability increase by 64% ( $\exp(0.0494*10)-1$ ).

entrepreneurs who own a house (even if big tech credit is not collateralised) and who are younger. Specifically, the probability to get big tech access is 1.75 times higher for entrepreneurs who own a house than for entrepreneurs who do not own a house ( $\exp(0.565)=1.75$ ). Interestingly, access is faster for female entrepreneurs even though they are typically less likely to have a bank account. In particular, the probability for a male entrepreneur to have access to big tech credit is only 0.85 times that of a female entrepreneur ( $\exp(-0.153)=0.85$ ). The speed of access to big tech credit is also negatively correlated with the distance of the firm's location to bank branches in km. This could be explained by the fact that most firms are located in metropolitan areas where distance to bank branches is minimal and the fact that most micro-enterprises are located in commercial centres where also bank branches are located.

#### 4.2 *Does the use of QR code in payment allow firm to use bank credit?*

The time a firm uses the QR code for payments does not seem to increase the probability of use of bank credit. Figure 4 reports the results based on the Kaplan-Meier survival estimate (green line). The Y-axis reports the probability of using bank credit, while the X-axis reports QR code duration. After one year from starting to use the QR code, the probability to use bank credit line is less than 1 per cent. This probability reaches only 2.5 percent in 3 years.<sup>7</sup> When focusing on unsecured (red) or secured (blue) bank credit, we find that for unsecured bank credit the probability reach 1.5 percent after three years, while it reaches less than 0.5 percent for secured bank credit. In summary, it seems that for a firm having a simple documentation of transaction volumes (obtained by using QR Code payments) does not alter significantly the probability for the firm to use bank credit. This reflect the fact that big tech credit is more similar to unsecured bank credit and that secured bank credit requires a collateral asset to pledge that in many cases it is not available to small entrepreneurs. Indeed, the use of the QR code payment does not increase the speed of access to secured credit. After three year from starting use the QR code, the probability to use secured credit is very close to zero. It is interesting to note that, also the spillover effects for use of unsecured bank credit, while statistically significant, remain very small.

---

<sup>7</sup> The results do not change dramatically if we use a duration model to test directly how much it takes for a firm from having access to the big tech credit line to using the bank credit, restricting the sample only to firms that that have access to big tech credit. After three years from the offer of the credit line, only 2.8 per cent of firms use bank credit.

The second column of Table 2 reports the corresponding regressions results. The time that elapses between when a firm starts to use the QR code and when she uses bank credit is strongly correlated with firm-specific variables (transaction volumes and network score). The other control variables have similar sign as in column I, with the notable exception of the gender variable. Male entrepreneurs tend to have a quicker use of bank credit. Columns III to V of Table 2 additionally control for (i) big tech credit access, (ii) big tech credit use and (iii) both. The inclusion of these variables allows us to test in a nested model how the use of the QR payment technology affects the use of bank credit for firms with no access to or no use of big tech credit and those with access or use. The results are very similar to those already discussed above. Both access to and use of big tech credit increases the speed with which firms can access bank credit, when included separately. When included together, the use of big tech credit increases the speed with which firms get access to bank credit while access reduces it. The probability to use bank credit for those firms who use big tech credit is 8.9 times that for firms which do not use it at that point of time ( $\exp(2.19)=8.93$ ). Controlling for the effects of big tech credit use, the probability to use bank credit for firms who have only access to big tech credit (but did not use it) is 0.7 that of other firms ( $\exp(-0.338)=0.71$ ). This is probably due to a demand effect as firms that had the opportunity to use big tech credit and did not use it have probably less need for bank credit as well.

Figures 5 and 6 show that there are substantial differences in the economic effect of access to or use of big tech credit for the use of bank credit. After three years from the use of the QR code, the probability to use bank credit is only 3% for firms with access to MYBank credit, while it is 1.5% for those with no access to big tech credit (Figure 5, left hand panel). Also in this case, spillover effects remain very low considering separately unsecured bank credit (centre panel) or secured bank credit (right hand panel).<sup>8</sup> Figure 6, on the other hand, shows that the use the big tech credit line increases significantly the probability of using of bank credit. After one year from starting use the QR codes, the probability to use bank credit line is around 8 per cent. This probability reaches 17 per cent after 3 years (left hand panel). By contrast, the probability for firms that do not use the credit line is always close to zero over the three

---

<sup>8</sup> The specific regressions for the two different bank credit types are reported in columns II of Table 3 (unsecured bank credit) and Table 4 (secured bank credit).

years. Qualitatively the results remain similar when considering separately unsecured bank credit (centre panel) or secured bank credit (right hand panel).<sup>9</sup>

Why is the spillover effect so different for a firm that uses the big tech credit line rather than for one that has simple access to it? One possible explanation for this difference is the positive signal given by the presence of the firm in the credit bureau. When a firm uses the big tech credit line it does enter the PBC credit bureau system and starts to have a footprint in the financial system. This footprint is visible also for banks and represents a positive signal on firm's quality, a result consistent with Agarwal et al (2021), though in a very different setting.<sup>10</sup>

Figures 4, 5 and 6 have already pointed to important differences between secured and unsecured bank credit. Tables 3 and 4 report the corresponding duration models.

The first columns of Tables 3 and 4 report the results of models that evaluate how QR code duration affects use of unsecured and secured bank credit, respectively and are equivalent to column (2) of Table 2. We find that firms with higher transaction volume and network scores, male and younger entrepreneurs and with house property access and use both unsecured and secured bank credit more rapidly. While a shorter distance to the nearest bank branch accelerates use of secured bank credit it does not accelerate use of unsecured bank credit. As in Table 2, we then add subsequently, a dummy indicating (i) access to and (ii) use of big tech credit, before (iii) including both.

### 4.3 *Disentangling demand and supply effects*

Our results could be driven by credit demand rather than information spillover effects. A firm who borrows from a big tech may simply have a higher credit demand compared to other firms that would not use such credit even if offered. Given their higher credit

---

<sup>9</sup> The specific regressions for the two different bank credit types are reported in columns III of Tables 3 (unsecured bank credit) and Table 4 (secured bank credit).

<sup>10</sup> A similar positive signaling effect is provided by mutual guarantee institutions (MGIs) in Italy. Mutual guarantee institution (MGI) members contribute to a guarantee fund which is then used as collateral to back loans granted to the members themselves. In this scheme, joint responsibility derives from firms' contribution to the mutual fund. Columba et al. (2010) show that small firms affiliated to MGIs pay less for bank credit compared with similar firms. The reason is that each member of the MGI is better informed than banks about other members' characteristics and behavior and grant access to the fund only if members are financially resilient. Be part of a MGI creates a sort of certification effects on banks.

demand, these firms (that use big tech credit) are more likely to ask for more credit also from traditional banks.

To tackle this issue, we focus our attention only on firms that have used big tech credit, distinguishing their behavior prior and after the use of big tech credit. In Table 5, we report the results of the duration model that describes the amount of time that elapses between when a firm starts to use the QR code and when she uses bank credit. We run the duration models for the three different types of bank credit (total, secured and unsecured) but only for the subset of firms that have used big tech credit in our sample period and therefore should have more similar demand needs.<sup>11</sup> We also include in the model directly the Big tech use dummy that allows us to consider the impact of the *QR Code Duration* on the event (use of bank credit) prior and after the use of big tech credit.

The results in Table 5 show that the use big tech credit is associated with firms more quickly gaining access to unsecured but not secured bank credit. Figure 7 reports, for each month that passes from the start of the use of QR code payment, the probability of having access to different form of bank credit. The results clearly show that even within the group of firms that use big tech credit at some point, the probability of bank credit use increases significantly after using big tech credit.<sup>12</sup>

The spillover effects caused by the use of big tech credit could be heterogeneous for different characteristics of QR Code merchants. To test for such differences, in Table 6 we include interaction terms between firm-specific characteristics and the big tech use dummy. The results indicate that the spillover effects from big tech use to bank credit use are larger for firms with female entrepreneurs, without house property and with lower network score. Other things being equal, these firms have more difficulties to have access to bank credit so the positive effects from using the QR code payments seems more helpful compared to other firms. Figure 8 reports the different probabilities for a spillover effect from big tech credit use to bank credit use for firms with different firm/entrepreneur's characteristics.

---

<sup>11</sup> For comparison, we also run similar models for the subset of firms that had access to MYbank credit (see Table 6)

<sup>12</sup> In robustness tests not reported here for the sake of brevity, results are confirmed also expanding our sample to all firms that gained access to MYbank credit even if they did not use it.

#### 4.4 Real effects of big tech credit

Next, we test whether the introduction of QR code payments and the use of big tech credit produces real effects for firms' activity. The first test uses the period around the introduction of the big tech loan product, while the second test considers the whole pre-Covid period (2017-2019); finally, we focus on the Covid-19 shock and compare the pre-pandemic to the pandemic period, considering firms with and without big tech credit.

##### 4.4.1 Introduction of MYbank credit

The first test focuses on the initial offering of big tech loans. Ant Group introduced the possibility of MYBank credit products to QR Code merchants at the end of June 2017 and started to supply loans in August 2017. We can use this exogenous shock to analyze the real effects of the provision of MYbank credit on firms' transactions volumes, comparing firms with and without credit. We exclude August 2017 from the analysis and compare 3 months before (2017.5-2017.7) and 3 months afterwards (2017.9-2017.11) the introduction of MYbank credit.

To rule out the possibility that a selection in the treatment of different firms may influence our results, we use a propensity score matching combined with a difference-in-differences type of analysis.

We first average selected firms' characteristics in the period before the launch of the new big tech loan product (pre-treatment period) and use  $\ln(\text{transaction volume})$  for the pre-treatment period and average transaction volumes, gender of the entrepreneur and the province where the firm is headquartered to predict the probability of being treated. Finally, we match each firm in the control group with one or more firm in the treatment group that has the closest score, that is the same probability of being treated. We estimate the following logit regression:

$$\begin{aligned} \text{Treat}_i = & \alpha + \beta_1 \ln(\text{trans volume})_{i, \text{average}} + \beta_2 \ln(\text{trans volume})_{i, \text{May } 2017} + \\ & \beta_3 \ln(\text{trans volume})_{i, \text{June } 2017} + \beta_4 \ln(\text{trans volume})_{i, \text{July } 2017} + \beta_5 \text{Male}_i + \beta_6 \text{Age}_i + \varepsilon_i \quad (4) \end{aligned}$$

where  $\text{Treat}_i$  is a dummy that equals 1 if firm  $i$  is in the treatment group (obtain the big tech credit access in August 2017) and 0 otherwise. Matching is done using a Nearest Neighbor approach with a conservative Caliper equal to 0.01. Finally, the matching is

done with replacement, so that there is more than one match between a firm in the treatment with a firm in the control group.

We then use the following difference-in-differences model.

$$\ln(\text{transaction volume})_{it} = \alpha + \beta * Post_t * Treat_i + u_i + s_t + \varepsilon_{it} \quad (5)$$

where the dependent variables is the logarithm of transaction volume for firm  $i$  and time  $t$ . The dummy  $Treat$  takes the value of 1 for those QR Code merchants who received MYbank credit approval in August 2017 (only in this initial month) and zero otherwise. The variable  $Post$  takes the value of 1 after August 2017 and zero before. We control for firm fixed effect  $u_i$  and time fixed effect  $s_t$ .  $\varepsilon_{it}$  is an error term. Standard errors are clustered at the firm level.<sup>13</sup>

The results in Column 1 of Table 7 show that the transaction volume increases 9.3 percent more for firms that had access to big tech credit (treated group) with respect to firms with similar characteristics which did not have access (control group). The left-hand panel of Figure 9 visualizes the behavior of the logarithm of transaction volumes of the two groups prior and after the launch of the offer of credit products by MYbank. The right-hand panel report the difference between the two firms' type and 95% confidence bands. While there is no difference between the treated and the control group until August 2017, the treatment group achieves higher levels of transactions thereafter.

The second test evaluates the effects of the provision of big tech credit over the period 2017.2-2019.12, i.e., beyond the initial period of introduction. Similarly to the test above, we use a propensity score matching combined with a diff-in-diff type of analysis:

$$\ln(\text{transaction volume})_{i,T+k} = \alpha + \beta * post_k * Treat_{i,T} + u_{iT} + s_k + \varepsilon_{it} \quad (6)$$

---

<sup>13</sup> The results are robust to the use of alternative cluster procedures, such as city\*time level.

Where the dependent variables is the logarithm of transaction volume for firm  $i$  and time  $T+k$ , while  $u_{iT}$  is Firm\*Time fixed effect, and  $s_k$  is the fixed effect to control period  $k$ .<sup>14</sup> The range of  $k$  is from -3 to 3 and  $\varepsilon_{it}$  is an error term.

The dummy  $Treat_{i,T}$  takes the value of 1 for a firm  $i$  who received MYbank credit approval in  $T$  (only in this initial month). Those firms with  $Treat_{i,T}$  equal to zero represent our control group, composed of QR Code merchants who did not get MYbank credit approval before  $T+3$  (but maybe later). The variable  $Post$  takes the value of 1 after  $T$  and zero elsewhere. We analyze the three months before the supply of credit in  $T$  and the three months afterwards. For each time  $T$ , we have a subsample which includes one control group and one treatment group.

The left-hand panel of Figure 10 shows that the treatment group of firms grows their transaction volume at a higher rate once it receives loans from MYbank. The results reported in column II or Table 7 and in the right hand panel of Figure 10 show that the transaction volume (significantly) increases (by around 4 percent more) for the treated group than for the control variable over the whole period.

#### 4.4.2 Real effects during the Covid19 pandemic

The Covid-19 pandemic has hit the Chinese economy hard, with some sectors affected particularly badly. Lockdown measures have reduced activity in transport, leisure and retail industries have collapsed. We now test wants if access to big tech credit provided a way to insulate the effects of the shock for SMEs.

Different from above, we use weekly data to capture the effect during the Covid-19 pandemic. Our sample period is from 30<sup>th</sup> Sep 2019 to 28<sup>th</sup> June 2020. In particular we compare the pre-Covid period (30<sup>th</sup> Sep 2019 to 19<sup>th</sup> Jan 2020) with the Covid period (26<sup>th</sup> Jan 2020 to 28<sup>th</sup> June 2020).

We consider an approach that is similar to that described above, using a propensity score matching approach and a difference in difference model (see equation 5). The dependent variables is the logarithm of transaction volume for firm  $i$  and time  $t$ . The treatment dummy  $Treat$  takes the value of 1 for those QR Code merchants who received

---

<sup>14</sup> It is worth noting that for test 2 we use a different set of fixed effects with respect to test 1. While in test 1 we evaluate a one-off shock, in test 2 we consider the effects over a time span of 36 months. For each group (control and treated) we evaluate seven periods (T-3, T-2, T-1, T, T+1, T+2, T+3) and therefore in regression (6), the level of observation is Firm (i) \* Time (T) \* Period (k). Following Brown and Earle (2017), we include in equation (6) both Firm\*Time fixed effect and period  $k$  fixed effects.

MYbank credit approval before 1<sup>st</sup> Oct 2019 and 0 otherwise. The variable *Post* takes the value of 1 after 26<sup>th</sup> Jan 2019 and zero elsewhere. Lock down policies in Chinese cities are captured by City\*time fixed effect to control for geographically different effects of the pandemic.

The results in Column III of Table 8 and illustrated in Figure 11 show that the transaction volume growth is around 20% percent higher for the treated group than for the control group during the pandemic, suggesting that the real effect duration Covid-19 are significantly large than that in normal time. It probably reflects the insulation value of big tech credit for firms to cope with the unexpected consequences of the shock. Figure 11 visualizes the behavior of the logarithm of transaction volumes (at the weekly level) of the two groups prior and after the Covid-19 shock.

## 5. Conclusions

The use of apps for mobile payments, through the so-called QR code, simplifies the collection of payments for firms at a reduced cost. This can help firms not only to increase transaction volumes but also to disclose their characteristics via payment data. Big tech firms can process these data – together with other non-traditional information collected on social media, search engines and e-commerce platform – to generate a credit score. Firms that are typically unbanked and lack of financial statements can have access to small loans that are not collateralised and typically used to adjust their liquidity needs. Overall the use of QR code could have positive effects for financial inclusion that go well beyond the simple efficient processing of transaction payments.

Using a unique dataset of around 500,000 Chinese firms that received credit from both an important big tech firm (Ant Group) and traditional commercial banks, this paper finds that: (i) the creation of a digital payment footprint allows firms to access other financial services and products offered by big techs. (ii) The use of big tech financial services and transaction data generated via QR code generates spillover effects on bank credit. The inclusion of big tech credit in the credit registry allows SMEs to be better screened/monitored by banks. These alleviate SMEs' asymmetric information problems with banks and allow SMEs to access also more traditional banking services. (iii) The real effects of QRcode credit are economically relevant, especially in the case of the Covid-19 shock.

## Chinese firms with QR code and access to big tech credit suffered less Covid-19 pandemic

Log(Transaction volumes in RMB, weekly data)

Figure 11

The vertical line indicates 26 Jan 2020 (Covid-19 measures were effective from this date onwards). The shaded area indicates 24 Jan–2 Feb 2020 (Chinese Spring Festival). The sample includes 8,800 randomly selected QRcodes of merchants which are used to construct weekly-firm level panel data. 4,400 QRcode merchants have access to big tech credit and others don't.
