

The energy-price channel of (European) monetary policy*

Gökhan Ider[†] Alexander Kriwoluzky[‡] Frederik Kurcz[§] Ben Schumann[¶]

February 28, 2023

Abstract

This study examines whether central banks can combat inflation that is caused by changes in energy prices. By using a high-frequency event study and a Vector Autoregression model, we find evidence that the Federal Reserve (FED) and the European Central Bank (ECB) are capable of doing so. In fact, changes in energy prices play a significant role in the transmission mechanism of monetary policy. Specifically, the energy-price channel of monetary policy operates mainly by decreasing the demand for energy, which in turn lowers its price. As one major source of energy, e.g. oil, is denominated in US Dollars, the Euro-Dollar exchange rate affects the euro area in two ways. An appreciation lowers local prices through cheaper imports, while also stimulating demand and subsequently increasing global and local prices. Our counterfactual analysis demonstrates that both effects are present, but the latter effect is stronger than the former.

Keywords: inflation, energy prices, monetary policy transmission mechanism

1 Introduction

Inflation has recently made a comeback, with a sharp rise in 2021, particularly after Russia’s invasion of Ukraine 1). One key debate in the euro area has been about whether the ECB’s instruments are effective in this situation, given that energy prices are the main driver of inflation. Those who argue that monetary policy is ineffective against energy-price driven inflation often suggest that the euro area should be considered a small open economy in the energy market, where changes in its demand would not affect the price of energy goods globally.¹ Furthermore, they contend that the demand for energy is independent of monetary policy, as households require heating and transportation. Additionally, while an appreciation of the Euro vis-a-vis the Dollar may lead to cheaper import prices of oil and other energy goods, which are largely traded in Dollar, there is a strong doubt that this price decrease will be passed on to consumers due to market frictions. In contrast, this debate has not taken place in the US. It is assumed that monetary policy has an effect on the global price of energy goods and that energy prices play an important role in monetary policy.

In this paper, we investigate the debate about the role of energy prices for the transmission of monetary policy empirically, where we use the crude oil price as a stand-in for global energy prices as prices of other energy goods such as gas tend to be highly correlated with global oil prices. In line with discussion, we focus on the euro area as the centre of the debate, and use the US mainly as a reference point. We begin with a high-frequency event study, where we regress changes in the oil price on monetary policy surprises, using both US and euro area data.

We find that a monetary policy tightening in both currency areas decreases the oil price, with the effect being similar in magnitude. This finding suggests that, like the US, the euro area is not a small open economy and that both have an impact on the global price of energy goods. To examine the role of the exchange rate in the euro area, we add an interaction term of monetary policy surprises and exchange rate changes to the regression. Remarkably, we find that the coefficient is significant and positive, indicating that while the appreciated exchange rate leads to lower local prices in the euro area, the stimulated demand for oil in the euro area pushes up global prices.

To differentiate between the different effects at work and quantify the importance of the change in energy prices for the transmission of monetary policy, we estimate a Bayesian proxy structural Vector Autoregression (VAR) model for the euro area. The model includes for each area its industrial production, headline CPI, a euro area energy price index, the Brent oil price as well as the Dollar-Euro exchange rate. We estimate a similar VAR model for the

¹When describing the ECB’s New Area Wide model Christoffel, Coenen, and Warne, 2008 state: “...the estimated version maintains the simplifying assumption that the euro area is a small open economy, motivated by the aforementioned fact that the ECB/Eurosystem staff projections are made conditional on assumptions regarding external developments.”.

US to contextualize the results for the euro area. The results show that the sub-components of the price index related to energy respond more strongly than the price index, suggesting that energy prices play an essential role in the transmission of monetary policy through the energy-price channel in the euro area as well as in the US.

Figure 1: Source: ECB

The identified VAR model enables us to conduct counterfactual experiments to differentiate between the various ways of the energy-price channel for the euro area, such as the large-open economy global price effect, as well as the global- and the local price effect of changes in the exchange rate. In the first counterfactual, we examine how a monetary policy would turn out if the oil price did not respond, assuming the euro area were a small open economy. Unsurprisingly, the price effects of the energy sub-component would be smaller. In the second counterfactual, we set the Dollar-Euro exchange rate to zero after a monetary policy shock in the euro area. The response of the oil price in this counterfactual is larger, and the decline of the HICP energy price index is stronger than in the baseline VAR model, suggesting that the global price effect of the exchange rate outweighs the effect of lower local prices. This finding is supported by a third counterfactual, where we keep the global price effects constant by setting the oil price in the counterfactual equal to its estimated impulse response after a monetary policy shock. The impulse response functions of the energy price index and the CPI decline less, suggesting that there is a local price effect of the exchange rate in place, indicating that cheaper import prices in the euro area due to an appreciation of the Euro vis-a-vis the Dollar are passed on to the consumer.

Importantly, the identified VAR model allows us to conduct counterfactual experiments to discriminate between the different ways of the energy-price channel for the euro area, e.g. the large-open economy global price effect, as well as the global- and the local price effect of changes in the exchange rate. We first ask, how would a monetary policy shock turn out, if

the oil price does not respond. In other words, if the euro area were a small open economy. Unsurprisingly, the price effects of the energy sub-component and thereby consumer price inflation would be smaller. In a second counterfactual, we assume that the Dollar-Euro exchange rate does not respond to a monetary policy shock in the euro area. Notably, the response of the oil price in this counterfactual is larger and the decline of the HICP energy price index stronger than in the baseline VAR model. Hence, the global price effect of the exchange rate, i.e. the price effect that comes from a stronger demand in the euro area due to its higher purchasing power outweighs the effect of lower local prices. This result is corroborated by a third counterfactual, in which we keep the global price effects constant, i.e. we set the oil price in the counterfactual equal to its estimated impulse response after a monetary policy shock. In addition, we again assume that the response of the exchange rate is zero. The counterfactual impulse response functions of the energy price index and the CPI decline less. Therefore, we conclude that there *is* a local price effect of the exchange rate in place, in other words, the cheaper import prices in the euro area due to an appreciation of the Euro vis-a-vis the Dollar is passed on to the consumer.

From the estimated impulse responses and the counterfactuals we thereby conclude that (i) the response of the global oil price to a EA monetary tightening is sizable and negative, which contradicts the SOE assumption (ii) a local price effect of the exchange rate is present as, conditional on the global price of oil, local energy prices and consumer prices rise in the absence of an exchange rate appreciation (iii) the global price effect of the exchange rate dominates the local price effect as the exchange rate appreciation boosts the global *and* local energy prices. As, despite the positive effect of the Euro appreciation, the global oil price falls after an EA monetary tightening we conclude that the largest effect comes from a simple decline in demand in the economy alongside the fact that neither the US nor the euro area is a small open economy.

The paper is structured in the following way. Section 2 sets out a simple model to illustrate how the energy channel of monetary policy can influence the economy in theory. In Section 3 we establish that US as well as euro area monetary policy shocks influence the oil price in a high-frequency study. The following Section 4 investigates how this effect plays out in a dynamic setting. Afterwards, in Section 5.1, we distinguish between the different effects monetary policy in the euro area has on energy prices by using a counterfactual analysis. The final section concludes.

2 A stylized open economy model with energy imports

This section presents a simple open economy to illustrate through which the energy-price channel of monetary policy can influence the economy. The starting point is a standard

closed economy, three equation New-Keynesian model for the home economy H .

$$y_{H;t} = \mathbf{E}_t(y_{H;t+1}) - \frac{1}{\sigma} (i_{H;t} - \mathbf{E}_t(\dot{C}_{H;t+1})) \quad (1)$$

$$\dot{C}_{H;t} = \mathbf{E}_t(\dot{C}_{H;t+1}) + \gamma y_{H;t} \quad (2)$$

$$i_{H;t} = \beta (\dot{C}_{H;t}) + r_{i;t} \quad (3)$$

Equations (1) and (2) are the standard log-linearized dynamic IS and New-Keynesian Phillips curve block, with $y_{H;t}$ denoting (domestic) output, $i_{H;t}$ the nominal interest rate of the home central bank, $\dot{C}_{H;t}$ the inflation rate of the domestically produced goods and $\dot{C}_{H;t+1}$ the inflation rate of the aggregate consumption basket defined below.

We complement the closed economy model with a highly stylized open economy dimension, where we assume that the home country H imports energy goods from the foreign country F . The *global* market price of these energy goods —expressed in foreign currency— is denoted by $p_{F;t}^{E:global}$, whereas the exchange rate is denoted by e_t . We express the exchange rate as amounts of foreign currency per unit of domestic currency, such that an increase of e_t corresponds to an appreciation of the domestic currency.

$$p_{H;t}^{E:local} = p_{F;t}^{E:global} \gamma_1 e_t \quad (4)$$

$$p_{H;t}^C = n(p_{F;t}^{E:local}) + (1 - n)p_{H;t} \quad (5)$$

$$y_{H;t}^E = \gamma_2 (p_{H;t}^C - p_{F;t}^{E:local}) + \gamma_3 y_{H;t} \quad (6)$$

$$p_{F;t}^{E:global} = \gamma_4 y_{H;t}^E + y_{F;t}^E \quad (7)$$

$$\mathbf{E}(e_{t+1}) - e_t = i_{F;t} - \gamma_5 i_{H;t} \quad (8)$$

Equation 4 defines the *local* price of energy import goods, which is measured in the home currency. Here, $\gamma_1 \in (0;1)$ measures the degree of exchange rate pass-through. If $\gamma_1 = 1$ all energy goods are priced and sticky in the foreign currency, which corresponds to the producer currency pricing (PCP) paradigm. If $\gamma_1 < 1$, some of the energy goods are priced and sticky in the home currency, which limits the impact the exchange rate has on the *local* import price. Equation 5 is the price of the aggregate home consumption basket where n defines the proportion of the basket that corresponds to the energy imports. Equation 6 defines the home country's demand for energy imports as a function of the overall activity and the relative price. In order to keep the model tractable and circumvent the need to model the foreign economy explicitly we assume that the global price of energy —measured in foreign currency— is an upward sloping function of the home country's $y_{H;t}^E$ and foreign country's $y_{F;t}^E$ energy demand as shown in 7. Lastly Equation 8 is a standard UIP equation, which implies that the home currency appreciates if the home central bank increases its interest rates as long as $\gamma_5 > 0$.

This minimal set of equation allows us to flesh out the assumptions underlying the different channels through which a central bank can influence global and local energy prices. From Equation 6 it becomes clear that a sufficient condition for the central bank to be able to affect the global energy price is the assumption that $\alpha_4 \neq 0$. In this case, as the country is not a small open economy, changes in the home countries economic activity ($y_{H,t}$) due to a monetary policy shock influence global energy prices ($p_{F,t}^{E,global}$). More precisely, a rise in interest rates, which causes a fall domestic activity leads to a fall in the demand for energy as long as energy consumption is somewhat proportional to economic activity (i.e. $\alpha_3 > 0$). This activity implied fall in the demand for energy causes a fall in the global price of energy.

Moreover, the rise in the interest rate leads to an appreciation of the exchange rate as long as $\alpha_5 > 0$. This appreciation has two, possibly opposing effects with respects to the local energy price and also drives a wedge between the evolution of the local and the global energy price. First, an appreciation of the exchange rates lowers the local energy price irrespective of the global price as long as there is some exchange rate pass-through (i.e. $\alpha_1 > 0$). This is the “local price effect of the exchange rate”. Second, this fall in the local price transmits to an increase in the home country’s energy demand if the demand for energy is not completely price inelastic (i.e. $\alpha_2 > 0$). This causes an increase in the global price of energy, which puts upward pressure on the local price. This is the “global price effect of the exchange rate”.

Table 1 summarizes the model assumption necessary in order for the central bank to be able to influence the *global and local* energy prices.

Effect on global price	Large open Economy ($\alpha_4 \neq 0$) + Elastic demand ($\alpha_2 \& \alpha_3 \neq 0$)
Effect on local price	FX-pass-through ($\alpha_1 \neq 0$) + FX appreciation ($\alpha_5 \neq 0$)

Table 1: Necessary assumptions for a central bank to influence global and local energy prices.

3 Monetary policy and oil prices - a high frequency analysis

In this section, we analyze whether US and euro area monetary policy shocks have an impact on global Brent oil prices. In order to establish a point of reference, we start with the US monetary policy. Most researcher would agree that the US is a large open economy and if any monetary policy decisions should affect the global oil price, it would have to be the ones by the Federal Reserve. Afterwards, we repeat the exercise with European data and add changes of the Dollar-Euro exchange rate to the regression to investigate its effect on the oil price as well.

3.1 High-frequency data for the US and the euro area

As construct a measure of the monetary surprise along the lines of Jarociński and Karadi, 2020 and use it as a proxy for the monetary policy shock. We choose the method of Jarociński and Karadi, 2020 for the following reasons. First, the maturity of the interest rate futures used to measure the policy surprise is the same for the US and the euro area: the three month Overnight Index Swap (OIS) rate for the ECB, and the three-month-ahead federal funds future rate (FF4) for the FED.² Second, the authors introduce a simple method, the "poor man's sign restrictions", to purge the surprises of any central bank information effects to generate "pure" monetary policy surprises. Third, this method is well established and commonly used in the literature, and does not require an individual specification for each country. Jarocinski and Karadi (2020), following the seminal work of Gürkaynak, Sack and Swanson (2005), measure the FED monetary policy surprises over a 30-minute window around the FOMC announcement. This is standard practice in the literature for FED surprises. Analogously to the FED, we use the same tight window around ECB policy announcements.³ Additionally, as a robustness check for the event study regression for the FED, we use the orthogonalized monetary policy surprises provided by Bauer and Swanson (2022). Regrettably, this design of monetary policy surprises is not available for the ECB policy announcements (yet).

We use tick data from the Refinitiv Tick History database to compute the variation in the Brent crude oil price in the windows around the ECB's and the FED's policy announcements. More precisely, we measure the price variation in the ICE Brent crude oil front-month futures (LCOc1), which is the benchmark global spot price quoted in the financial news, and has the highest liquidity. Thereby, we closely follow the methodology outlined in the online appendix of Altavilla et al. (2019) to measure a pre- and post-announcement price. For the euro area, we compute the Dollar-euro exchange rate variation around policy announcements of the ECB. **data source**

3.2 Event study for US monetary policy

In order to study the effects of US monetary policy on global oil prices, we estimate the following high-frequency regression:

$$p_t = \alpha + \beta mps_t + \epsilon_t \quad (9)$$

where p_t is the variation in the Brent crude oil price, and mps_t is the FED monetary policy surprise for each FOMC announcement in day t . Table 2 presents the results for the FED

²The intraday variation in the three month OIS rate around ECB policy announcements is provided by the EA-MPD database from Altavilla et al. (2019). The intraday variation in the FF4 around FOMC announcements is provided by Gürkaynak, Sack and Swanson (2005).

³Specifically, we use the press release window from the EA-MPD.

event study regressions (Equation 9) with different policy surprises. The first column is for the regression with the "pure" monetary policy surprise (FF4 with "poor man's sign restrictions") as in Jarocinski and Karadi (2020). The second column is for the regression with the orthogonalized policy surprise from Bauer and Swanson (2022). The event study regressions cover the longest sample that data is available for.⁴ Furthermore, we exclude the few event days early in the sample where there are no LCOc1 trades in the tight window around the FOMC announcement.

Table 2: Coefficient estimates from the Brent crude oil price event study regressions $p_t = \hat{\alpha} + mps_t + \epsilon_t$ for the FED, where t indexes FOMC announcements. *Notes:* Each column represents the use of a different monetary policy surprise as a regressor. mps_{FF4}^{pm} is the change in the three-month-ahead federal funds future rate (FF4) with poor man's sign restrictions as in Jarocinski and Karadi (2020). mps° is the orthogonalized monetary policy surprise uncorrelated with macroeconomic and financial data observed before the FOMC announcement from Bauer and Swanson (2022). Heteroskedasticity-consistent standard errors are reported in parentheses.

	mps_{FF4}^{pm}	mps°
$\hat{\alpha}$	2.15 (1.01)	2.23 (0.83)
R^2 (%)	2.21	3.21
Sample	1996:1-2019:12	1996:1-2019:12
N	187	187

We find that a contractionary monetary policy surprise by the FED decreases the global oil price. The coefficient, $\hat{\alpha}$, is negative and significantly different from zero. This finding documents, as expected, that the US is not a small open economy in the global oil market, but an important player on the market.

3.3 Event study for the euro area

Does the result for the US carry over to the euro area? We now look into euro area data to answer this question. In particular, we estimate an event study regression for the ECB of the form:

$$p_t = \hat{\alpha} + mps_t + mps_t e_t + \epsilon_t \quad (10)$$

⁴Intraday data is available for the ICE Brent crude oil front-month futures (LCOc1) from the Refinitiv Tick History database from 1996. Intraday variations in both FED monetary policy surprises are available until December 2019.

where p_t is the intraday variation in the Brent crude oil price, mps_t is the “pure” ECB monetary policy surprise (i.e. poor man’s three month OIS rate), and e_t is the intraday variation in the euro-US dollar exchange rate (EUR/USD) for the tight window around the ECB policy announcement on day t . Additional to the monetary policy surprise as a regressor, we include an interaction term for the monetary policy surprise with the EUR/USD variation.⁵

Table 3 presents the results for the event study regression for the ECB (Equation 10) for different sample periods. The first column is for the longest sample that the data is available for the ECB monetary policy surprises. The second column is for the sample excluding the pandemic period. The third column is for the sample starting in January 2002. In their event study analyses, Altavilla et al. (2019), Andrade and Ferroni (2021), and Kersefischer (2022) use the ECB policy surprises as a regressor starting from 2002, citing liquidity issues regarding the euro area OIS contracts prior to 2002, as the reason. Furthermore, we exclude the three coordinated rate cuts among major central banks in our sample, following Jarocinski and Karadi (2020).

Table 3: Coefficient estimates β and γ from the Brent crude oil price event study regressions $p_t = \beta + mps_t + mps_t e_t + \gamma t$ for the ECB, where t indexes ECB policy announcements. *Notes:* Each column presents the event study regression for a different sample period. mps_t is the high frequency change in the three month Overnight Index Swap (OIS) rate with poor man’s sign restrictions as in Jarocinski and Karadi (2020). Heteroskedasticity-consistent standard errors are reported in parentheses.

	(1)	(2)	(3)
$\hat{\beta}$	2.05	1.69	2.51
	(0.83)	(0.83)	(1.22)
$\hat{\gamma}$	4.06	4.17	3.94
	(0.70)	(0.69)	(1.35)
R^2 (%)	3.00	2.78	3.58
Sample	1999:1-2021:12	1999:1-2019:12	2002:1 - 2021:12
N	278	262	212

We find first that a contractionary monetary policy surprise by the ECB leads to a decline on the global oil price. Remarkably, the size of the effect is of similar magnitude as the one of the US monetary policy. Therefore, not only is the euro area not a small open economy,

⁵The intraday variation in the EUR/USD in the tight window around the ECB policy announcement is a function of the monetary policy surprise. Therefore, simply augmenting the regression equation with the EUR/USD as an independent regressor would yield biased estimates.

but it has on the oil market an influence comparable to the one of the US. A second result is the significantly positive coefficient in front of the interaction term for monetary policy and the change in the exchange rate.⁶ This result suggests that the global price effect of the exchange rate change is at work, as demand increases due to cheaper import prices after an appreciation of the Euro vis-a-vis the Dollar, which in turn leads to higher global oil prices.

4 The energy-price channel in a dynamic setting

Section 3 shows that US as well as euro area monetary policy shocks have an immediate impact on global oil prices. In this section, we investigate how the immediate effects play out dynamically. To this end, we set up, estimate a Bayesian proxy SVAR model, and present the results in this section. We analyse it first for the euro area and afterwards for the US to put the euro area results in a context.

4.0.1 The Bayesian Proxy Structural Vector Autoregression (BP-SVAR) model

Since we will later also identify an oil supply news shock in addition to a monetary policy shock to conduct counterfactuals, we lay out the BP-SVAR model for the general case with k proxy variables.

Following the notation of Rubio-Ramirez, Waggoner, and Zha, 2010, consider without loss of generality the structural VAR model with one lag and without deterministic terms

$$\mathbf{y}_t^\ell \mathbf{A}_0 = \mathbf{y}_{t-1}^\ell \mathbf{A}_1 + \boldsymbol{\varepsilon}_t^\ell; \quad \boldsymbol{\varepsilon}_t^\ell \sim N(\mathbf{0}; \mathbf{I}_n); \quad (11)$$

where \mathbf{y}_t is an $n-1$ vector of endogenous variables and $\boldsymbol{\varepsilon}_t$ an $n-1$ vector of structural shocks. The BP-SVAR framework builds on the following assumptions in order to identify k structural shocks of interest: There exists a $k-1$ vector of proxy variables \mathbf{m}_t that are (i) correlated with the k structural shocks of interest $\boldsymbol{\varepsilon}_t$ and (ii) orthogonal to the remaining structural shocks $\boldsymbol{\varepsilon}_t^\ell$. Formally, the identifying assumptions are

$$E[\boldsymbol{\varepsilon}_t \mathbf{m}_t^\ell] = \mathbf{V}_{(k-k)}; \quad (12a)$$

$$E[\boldsymbol{\varepsilon}_t^\ell \mathbf{m}_t^\ell] = \mathbf{0}_{((n-k)-k)}; \quad (12b)$$

and represent the relevance and the exogeneity condition, respectively.

Denote by $\tilde{\mathbf{y}}_t^\ell = (\mathbf{y}_t^\ell; \mathbf{m}_t^\ell)$, by $\tilde{\mathbf{A}}$ the corresponding $\tilde{n} \times \tilde{n}$ coefficient matrices with $\tilde{n} = n+k$, by $\tilde{\boldsymbol{\varepsilon}}_t = (\boldsymbol{\varepsilon}_t^\ell; \mathbf{v}_t^\ell)^\ell \sim N(\mathbf{0}; \mathbf{I}_{n+k})$, where \mathbf{v}_t is a $k-1$ vector of measurement errors (see below).

⁶As a robustness check, we additionally estimate the same event study regressions replacing the EUR/USD exchange rate with the US Dollar index (DXY) to capture the total variation in the US-Dollar in the narrow event window around the ECB policy announcement. The results are robust to this specification.

The augmented structural VAR model is then given by

$$\tilde{\mathbf{y}}_t^\ell \tilde{\mathbf{A}}_0 = \tilde{\mathbf{y}}_{t-1}^\ell \tilde{\mathbf{A}}_1 + \tilde{\boldsymbol{\varepsilon}}_t^\ell. \quad (13)$$

To ensure that the augmentation with equations for the proxy variables does not affect the dynamics of the endogenous variables, the coefficient matrices $\tilde{\mathbf{A}}_\cdot$ are specified as

$$\tilde{\mathbf{A}}_\cdot = \begin{array}{c} \textcircled{\mathbf{O}} \\ \textcircled{\mathbf{B}} \end{array} \begin{array}{c} \mathbf{A}_\cdot \\ \mathbf{0} \end{array} \begin{array}{c} \mathbf{\Gamma}_{\cdot,1} \\ \mathbf{\Gamma}_{\cdot,2} \end{array} \begin{array}{c} \mathbf{1} \\ \mathbf{A}_\cdot \end{array}; \quad \cdot = 0;1; \quad (14)$$

$\begin{matrix} (n \times n) & (n \times k) \\ (k \times n) & (k \times k) \end{matrix}$

The zero restrictions on the lower left-hand side block imply that the proxy variables do not enter the equations of the endogenous variables. The reduced form of the model is

$$\tilde{\mathbf{y}}_t^\ell = \tilde{\mathbf{y}}_{t-1}^\ell \tilde{\mathbf{A}}_1 \tilde{\mathbf{A}}_0^{-1} + \tilde{\boldsymbol{\varepsilon}}_t^\ell \tilde{\mathbf{A}}_0^{-1}. \quad (15)$$

Because the inverse of $\tilde{\mathbf{A}}_0$ in Equation (14) is given by

$$\tilde{\mathbf{A}}_0^{-1} = \begin{array}{c} \mathbf{A}_0^{-1} \\ \mathbf{0} \end{array} \begin{array}{c} \mathbf{A}_0^{-1} \mathbf{\Gamma}_{0,1} \mathbf{\Gamma}_{0,2}^{-1} \\ \mathbf{\Gamma}_{0,2}^{-1} \end{array}; \quad (16)$$

the last k equations of the reduced form of the VAR model in Equation (15) read as

$$\mathbf{m}_t^\ell = \tilde{\mathbf{y}}_{t-1}^\ell \tilde{\mathbf{A}}_1 \begin{array}{c} \mathbf{A}_0^{-1} \mathbf{\Gamma}_{0,1} \mathbf{\Gamma}_{0,2}^{-1} \\ \mathbf{\Gamma}_{0,2}^{-1} \end{array} + \boldsymbol{\varepsilon}_t^\ell \mathbf{A}_0^{-1} \mathbf{\Gamma}_{0,1} \mathbf{\Gamma}_{0,2}^{-1} + \boldsymbol{\nu}_t^\ell \mathbf{\Gamma}_{0,2}^{-1}; \quad (17)$$

which shows that in the BP-SVAR framework the proxy variables may be serially correlated and affected by past values of the endogenous variables and measurement error.

Ordering the structural shocks so that $\boldsymbol{\varepsilon}_t = (\boldsymbol{\varepsilon}_t^\ell; \boldsymbol{\varepsilon}_t^\ell)^\ell$ yields

$$E \boldsymbol{\varepsilon}_t \boldsymbol{\varepsilon}_t^\ell = \begin{array}{c} \textcircled{\mathbf{O}} \\ \textcircled{\mathbf{V}} \end{array} \begin{array}{c} \mathbf{1} \\ \mathbf{A}_\cdot \end{array}; \quad (18)$$

$\begin{matrix} (n \times k) & (k \times k) \end{matrix}$

The first equality is obtained using Equation (17) and because the structural shocks $\boldsymbol{\varepsilon}_t$ are by assumption orthogonal to \mathbf{y}_{t-1} and $\boldsymbol{\nu}_t$. The second equality is due to the exogeneity and relevance conditions in Equations (12a) and (12b). Equation (18) shows that the identifying assumptions imply restrictions on the last k columns of the contemporaneous structural impact coefficients in $\tilde{\mathbf{A}}_0^{-1}$. In particular, if the exogeneity condition in Equation (12b) holds, the first $n - k$ rows of the upper right-hand side sub-matrix $\mathbf{A}_0^{-1} \mathbf{\Gamma}_{0,1} \mathbf{\Gamma}_{0,2}^{-1}$ of $\tilde{\mathbf{A}}_0^{-1}$ in Equation (16) are zero. From the reduced form in Equation (15) it can be seen that this implies that the

first $n - k$ structural shocks do not impact contemporaneously the proxy variables. In turn, if the relevance condition in Equation (12a) holds, the last k rows of the upper right-hand side sub-matrix $\mathbf{A}_0^{-1}\mathbf{\Gamma}_{0,1}\mathbf{\Gamma}_{0,2}^{-1}$ of $\tilde{\mathbf{A}}_0^{-1}$ are different from zero. From the reduced form in Equation (15) it can be seen that this implies that the last k structural shocks impact the proxy variables contemporaneously. The Bayesian estimation algorithm of Arias, Rubio-Ramírez, and Waggoner, 2021 determines the estimates of \mathbf{A}_0 and $\mathbf{\Gamma}_{0,\cdot}$ such that the restrictions on $\tilde{\mathbf{A}}_0^{-1}$ implied by Equations (12a) and (12b) as well as on $\tilde{\mathbf{A}}_0$ in Equation (14) are simultaneously satisfied, and hence the estimation identifies the structural shocks ϵ_t .

The BP-SVAR framework of Arias, Rubio-Ramírez, and Waggoner, 2021 has numerous advantages. In short: First, the BP-SVAR framework allows us to refrain from imposing potentially contentious recursiveness assumptions between the endogenous variables when multiple structural shocks are point-identified—as done below—with multiple proxy variables. Second, the single-step estimation of the BP-SVAR model is more efficient and facilitates coherent inference; in fact, the Bayesian set-up allows exact finite sample inference, and does not require an explicit theory to accommodate weak instruments. Third, the BP-SVAR framework is relatively flexible in that Equation (17) allows the proxy variables to be serially correlated and be affected by measurement error.

4.1 Data and specification

Our baseline monetary SVAR model for the Euro Area contains six variables and additionally the high-frequency surprises to identify an ECB monetary policy shock. We follow a large literature on monetary policy high-frequency identification by including an interest rate as an indicator of the monetary policy stance, industrial production as a proxy for economic activity, a measure of the price level, as well as a credit spread (e.g., Gertler and Karadi (2015), Jarociński and Karadi (2020), and Bauer and Swanson (2022)). To this standard model, first, we add an exchange rate and the price of oil. In a subsequent step we also additionally add measures of consumer energy prices.

Specifically, the model includes the 1-year constant maturity yield on German Bunds as the monetary policy indicator. Since our sample contains a considerable period of time at the zero lower bound (ZLB), it is important to us a longer rate that remains a valid measure of the monetary policy stance at the ZLB. Economic activity is measured by the Euro Area Industrial production excl. construction index. Since our main interest is on energy price inflation, we use the (headline) Harmonized Index of Consumer Prices (HICP) for the general price level, because of its fine categories that allow us to later study energy-intensive subcomponents. The BBB bond spread is used to capture financial conditions, a channel which has been found to be important in monetary transmission (Gertler and Karadi (2015), Caldara and Herbst (2019)). We use the Brent crude oil price as a measure for global oil prices and the

US-Euro exchange rate, since oil is usually traded in US-Dollars. The monetary policy proxy is the same as in section 3. All data is monthly and enters the SVAR in log-levels (\ln), except for the interest rate, the credit spread, and the proxy, which enter in levels. Further details on the dataset can be found in the appendix.

The SVAR for the euro area is estimated on a sample from January 1999 to February 2020, thus leaving out the extraordinary volatility in the data induced by the Covid-19 pandemic.⁷ The model has 12 lags and includes a constant. Finally, we use flat priors for estimating the SVAR parameters. In addition, a relevance threshold is imposed to express the prior belief that the proxy is informative to identify monetary policy shocks. We set a prior $\gamma = 0.1$, imposing a threshold that the identified structural monetary policy shocks account for at least 10% of the variance in the proxy.^{8 9}

4.2 Dynamic effect of a monetary policy shock

Figure 2 presents our baseline estimates of the effects of a one standard deviation contractionary monetary policy shock for the euro area. In case of the euro area the 1-year yield of the Bund increases by roughly 3 basis points on impact, which quickly reverts back to zero and turns slightly negative, with an overall shape very similar to Jarociński and Karadi (2020). Industrial production falls significantly and remains depressed for about 1.5 years. The price level falls significantly as well, reaching a trough after about 20 months. The credit spread is mildly positive after the monetary policy shock but does not respond significantly in our sample (not shown).¹⁰ Turning to the exchange rate, as expected, the Euro appreciates against the US-Dollar by about one percent and remains elevated significantly for a year. Our main result in the SVAR analysis is a sizable fall in measures for local and global energy prices. The oil price (in US-Dollars) falls strongly by 2.5 percent and reverts back to zero within 10 months. Moreover, the local energy price index, measured by the HICP energy component, falls significantly and by much more compared to the headline index.

A very similar picture arises when we conduct the exercise for the US. Figure 3 presents the effects of a US monetary policy shock. Importantly, the (global) price of oil in US-Dollars declines significantly, in line with weakening domestic demand in the US and an appreciation of the US NEER. To summarize, the results in total are very similar for both countries. The finding of the dynamic model corroborates the results from Section 3: both areas exert effects

⁷The VAR model for the US is estimated on the longer sample from January 1990 to December 2019.

⁸Compared to the literature this is a weak requirement (cf. Arias, Rubio-Ramírez, and Waggoner (2021) and the ‘high-relevance’ prior of Caldara and Herbst (2019)). In a robustness exercise, we show that reducing the relevance condition to $\gamma = 0.001$ does not change our results.

⁹The results are very similar for the sample we use for the Euro Area, January 1999 to December 2019, as well as when the poor man’s proxy of Jarociński and Karadi (2020) is used instead of the proxy by Bauer and Swanson (2022).

¹⁰Due to space constraints we relegate the spreads for both the Euro Area and the US in appendix XX.

on global energy prices in comparable magnitude. What the impulse response functions show in addition is that in both areas energy prices respond stronger than the CPI. Therefore, in the euro area as well as in the US monetary policy is transmitted via the change in energy prices.

Figure 3: Baseline United States SVAR model. Notes: Impulse response functions to a one standard deviation monetary policy shock. Point-wise posterior means along with 68% and 90% point-wise probability bands. Horizon in months.

5 Dissecting the energy-price channel in the euro area

The previous sections have established that the energy-price channel is relevant, not only for the Federal reserve, but for the ECB as well. Section 2 has outlined that the energy-price channel effects the economy in different ways. In this section, we conduct three counterfactual experiments to distinguish the importance of the different components of the energy-price channel.

In particular, we use Structural Shock Counterfactuals (SSC), Structural Scenario Analysis (SSA) and Minimum Relative Entropy (MRE) methods to simulate a counterfactual monetary policy shock. Although the three methods which we describe in more detail below may seem fundamentally different, they are indeed related. In particular, any counterfactual scenario can be characterized by (i) the *counterfactual* outcome that is supposed to be different from to the *factual/true* outcome and (ii) the circumstances that are allowed to change in order to for the counterfactual outcome to materialize. While the three methods share the same counterfactual outcome, they fundamentally differ in the circumstances that are allowed to change.

5.1 Computing SVAR counterfactuals

The VAR model in Equation (11) can be iterated forward and re-written as

$$\mathbf{y}_{T+1:T+h} = \mathbf{b}_{T+1:T+h} + \mathbf{M}^0_{T+1:T+h} \mathbf{y}_{T+1:T+h}^0 \quad (19)$$

where the $nh \times 1$ vector $\mathbf{y}_{T+1:T+h}^0 = [\mathbf{y}_{T+1}^0; \mathbf{y}_{T+2}^0; \dots; \mathbf{y}_{T+h}^0]'$ denotes future values of the endogenous variables, $\mathbf{b}_{T+1:T+h}$ an autoregressive component that is due to initial conditions as of period T , and the $nh \times 1$ vector $\mathbf{y}_{T+1:T+h}^0 = [\mathbf{y}_{T+1}^0; \mathbf{y}_{T+2}^0; \dots; \mathbf{y}_{T+h}^0]'$ future values of the structural shocks. The $nh \times nh$ matrix \mathbf{M} reflects the impulse responses and is a function of the structural VAR parameters $\text{vec}(\mathbf{A}_0; \mathbf{A}_1)$.

Assume for simplicity of exposition but without loss of generality that the VAR model in Equation (11)—which does not have deterministic components—is stationary and in steady state in period T so that $\mathbf{b}_{T+1:T+h} = \mathbf{0}$. In this setting, an impulse response to the i -th structural shock over a horizon of h periods coincides with the forecast $\mathbf{y}_{T+1:T+h}$ conditional on $\mathbf{y}_{T+1:T+h}^0 = [\mathbf{e}_i; \mathbf{0}_{1 \times (h-1)}]'$, where \mathbf{e}_i is an $n \times 1$ vector of zeros with unity at the i -th position. For example, for the impulse response to a monetary policy shock we have $\frac{mp}{T+1} = 1$, $\frac{mp}{T+s} = 0$ for $s > 1$ and $\frac{mp}{T+s} = 0$ for $s > 0$, $\frac{mp}{T+s} \notin mp$.

For later reference we follow Breitenlechner, Georgiadis, and Schumann, 2022 and define the “contribution” of our channel of interest as the difference between the impulse responses of endogenous variables to a monetary policy shock in the baseline denoted by $\mathbf{y}_{T+1;T+h}$ and in a counterfactual denoted by $\mathfrak{y}_{T+1;T+h}$. The defining feature of the counterfactual is that the response of a one or more variables is restricted to be at a specific value.

5.1.1 SSA/SSC counterfactuals:

For SSA/SSC counterfactuals the VAR model is unchanged in the counterfactual in terms of the structural parameters and hence \mathbf{M} in Equation (19). Therefore, in order for the impulse response $\mathfrak{y}_{T+1;T+h}$ to satisfy counterfactual constraints additional shocks in $\mathbf{e}_{T+1;T+h}$ must be allowed to materialise over horizons $T+1; T+2; \dots; T+h$. Thus the structural shocks are the “circumstances” that are allowed to change in order for the counterfactual outcome to materialize.

Building on Waggoner and Zha, 1999, Antolin-Diaz, Petrella, and Rubio-Ramirez, 2021 show how to obtain $\mathfrak{y}_{T+1;T+h}$ subject to constraints on the paths of a subset of the endogenous variables

$$\overline{\mathbf{C}}\mathfrak{y}_{T+1;T+h} = \overline{\mathbf{C}}\mathbf{M}^{\ell}\mathbf{e}_{T+1;T+h} \quad N(\overline{\mathbf{f}}_{T+1;T+h}; \overline{\mathbf{\Omega}}_f); \quad (20)$$

where $\overline{\mathbf{C}}$ is a $k_o \times nh$ selection matrix, $\overline{\mathbf{f}}_{T+1;T+h}$ is a $k_o \times 1$ vector and $\overline{\mathbf{\Omega}}_f$ a $k_o \times k_o$ matrix, and subject to constraints on the structural shocks given by

$$\mathbf{\Xi}\mathbf{e}_{T+1;T+h} \quad N(\mathbf{g}_{T+1;T+h}; \mathbf{\Omega}_g); \quad (21)$$

where $\mathbf{\Xi}$ is a $k_s \times nh$ selection matrix, $\mathbf{g}_{T+1;T+h}$ a $k_s \times 1$ vector, and $\mathbf{\Omega}_g$ a $k_s \times k_s$ matrix. In our context, Equation (20) imposes the counterfactual constraint that the the response of the constrained variable is nil, and Equation (21) the constraint that some structural shocks may not be in the set of offsetting shocks that materialise along the impulse response horizon to enforce the counterfactual constraint. Depending on the structure of Equation (21) we call a counterfactual SSC or SSA. In particular, if only a specific subset of structural shocks is allowed to materialize then we call the counterfactual simulation a Structural Shock Counterfactual (SSC) and if *all* shocks can occur along the impulse response horizon we label it a Structural Shock Analysis (SSA).

Antolin-Diaz, Petrella, and Rubio-Ramirez, 2021 show how to obtain the solution to the SSA/SSC problem in terms of a $\mathbf{e}_{T+1;T+h}$ which satisfies the counterfactual constraints. The counterfactual impulse response is then given by $\mathfrak{y}_{T+1;T+h} = \mathbf{M}^{\ell}\mathbf{e}_{T+1;T+h}$. While there may be many solutions to the problem, Antolin-Diaz, Petrella, and Rubio-Ramirez, 2021 show that their proposed solution minimises the Frobenius norm of the deviation of the distribution of the structural shocks under the counterfactual from the baseline. Intuitively, this means

the counterfactual shocks chosen are those that are minimally different in terms of mean and variance from the baseline and as such the counterfactual circumstances (the structural shocks) deviate as little as possible from the factual circumstances.¹¹

5.1.2 MRE counterfactuals:

In the existing literature MRE is used to incorporate restrictions derived from economic theory into a conditional forecast (See Cogley and Sargent, 2005, Robertson, Tallman, and Whiteman, 2005 and Giacomini and Ragusa, 2014 for forecasting applications.) Similar in spirit, we use MRE to generate a counterfactual conditional forecast based on our baseline conditional forecast in Equation (19) that represents the impulse responses to a monetary policy shock. As in the SSA/SSC counterfactuals our counterfactual scenario is characterized (i) by the counterfactual outcome that is restricted to be different than the factual outcome and (ii) the circumstances that are allowed to change. While the restrictions we place on the path of specific variables are the same for the SSA/SSC and MRE methods, the circumstances that are allowed to change are different. In particular, in the MRE counterfactual no additional structural shocks materialize over the horizon of the impulse response. The circumstances that are allowed to change rather are the impulse responses in the matrix \mathbf{M} in Equation (19), which themselves are a function of the VAR parameters θ .

To be more precise, again conceive of an impulse response as the conditional forecast $\mathbf{y}_{T+1:T+h}$, where we have for $\mathbf{y}_{T+1:T+h}$ that $\frac{mp}{T+1} = 1$, $\frac{mp}{T+s} = 0$ for $s > 1$ and $\dot{\mathbf{y}}_{T+s} = 0$ for $s > 0$, $\dot{\mathbf{y}} \notin mp$. Our posterior belief about the actual effects of a monetary policy shock after h periods is given by

$$f(\mathbf{y}_{T+h} | \mathbf{y}_{1:T}; I_a; \theta_{T+1:T+h}) \propto \rho(\theta) \cdot \dot{\mathbf{y}}(\mathbf{y}_{1:T}; I_a) \quad ; \quad (22)$$

where $\rho(\theta)$ is the prior about the structural VAR parameters, I_a our identifying assumptions, and $\dot{\mathbf{y}}$ the volume element of the mapping from the posterior distribution of the structural VAR parameters to the posterior distribution of the impulse response \mathbf{y}_{T+h} . MRE determines the posterior beliefs about the effects of a monetary policy shock \mathbf{y}_{T+h} in a counterfactual VAR model with structural parameters θ by

$$\begin{aligned} & \underset{\theta}{\text{Min}}_{\dot{\mathbf{y}}} D(f | \dot{\mathbf{y}}) \quad s.t: \\ & \int f(\mathbf{y}) \dot{\mathbf{y}}^{tar} d\mathbf{y} = E(\dot{\mathbf{y}}^{tar}) = 0; \quad \int f(\mathbf{y}) d\mathbf{y} = 1; \quad f(\mathbf{y}) \geq 0; \end{aligned} \quad (23)$$

where $D(\cdot)$ is the Kullback-Leibler divergence—the ‘relative entropy’—between the counter-

¹¹See Appendix D for further technical details and the specification of $\bar{\mathbf{C}}$, $\bar{\mathbf{f}}_{T+1:T+h}$, $\bar{\boldsymbol{\Xi}}$, $\bar{\mathbf{g}}_{T+1:T+h}$, $\bar{\boldsymbol{\Omega}}_g$ and $\bar{\boldsymbol{\Omega}}_f$ in the baseline and the counterfactual conditional forecast in our application.

factual and baseline posterior beliefs (the subscripts in Equation (23) are dropped for simplicity). In general, there are infinitely many counterfactual beliefs f that satisfy the constraint $E(\mathbf{y}_{T+h}^{tar}) = T_{t+h}$, where T_{t+h} is the counterfactual constraint. The MRE approach disciplines the choice of the counterfactual posterior beliefs f by requiring that they are *minimally* different from the baseline posterior beliefs f in an information-theoretic sense. Intuitively, MRE determines the counterfactual VAR model in which the constrained variable is at its target but whose dynamic properties in terms of impulse responses are otherwise minimally different from those of the actual VAR model.

5.2 Counterfactual I: the euro area as a SOE

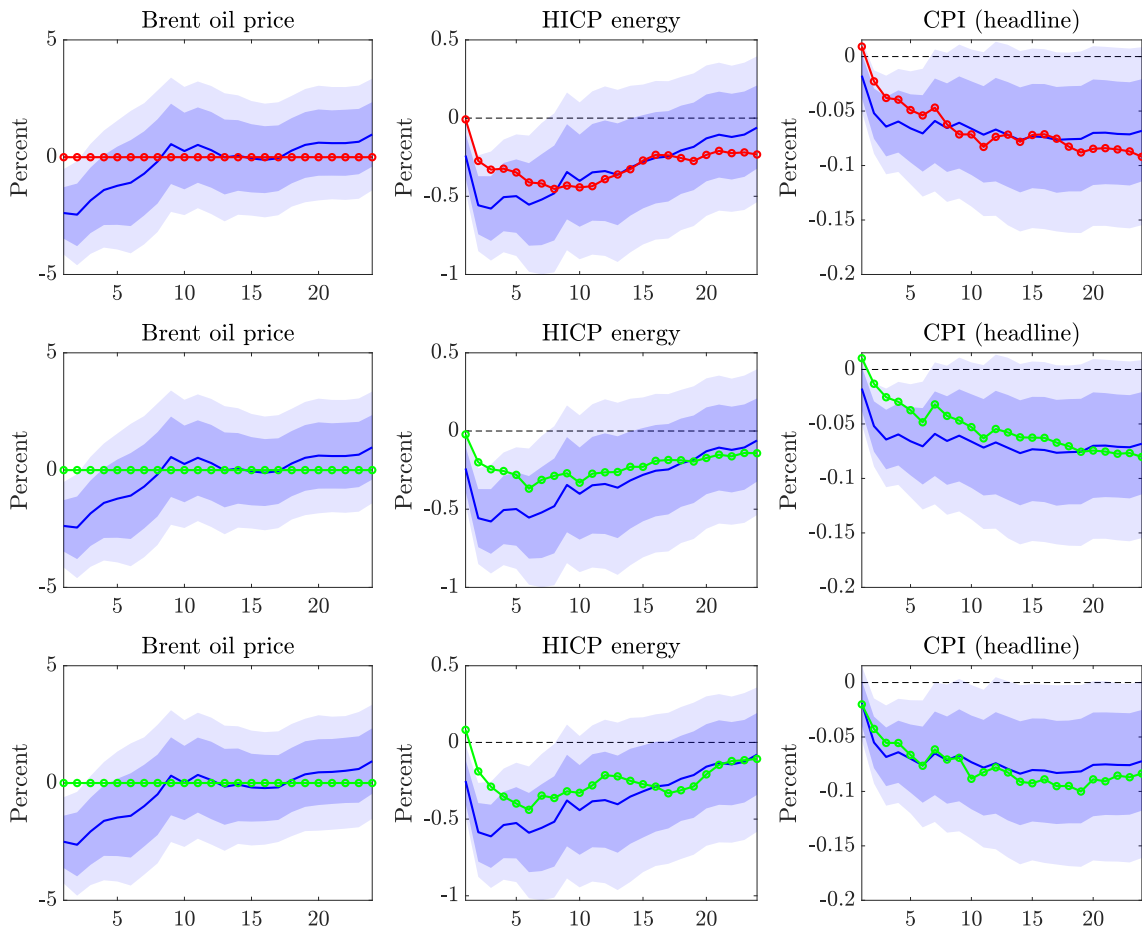

In a first counterfactual, we ask how the economy would respond to a monetary policy shock, if the euro area were a small open economy. To this end, we simulate a counterfactual monetary policy shock that —as implicitly assumed in many models of the euro area— does not impact global energy prices as measured by the Brent Oil Price in our model. In this counterfactual, we employ the SSA, SSC, and MRE method. While the SSA and MRE method are implemented exactly as described above the SSC counterfactual needs a bit more detail. In particular, we identify an additional oil supply news shock using the proxy variable of Känzig, 2021 and impose that this shock materializes along the impulse horizon in order to stabilize the response of the oil price.

The results from this exercise for the MRE, SSA and MRE case are shown in figure 4. Irrespective of the method employed it becomes apparent that the local energy price —as measured by the energy component of the HICP — and to a lower extent even aggregate HICP inflation in the Euro Area would react substantially less to a contractionary EA monetary policy shock if this shock would not affect the global oil price. Thus imposing the SOE assumption could potentially cause models to *underestimate* the impact central bank decisions could have on domestic energy and consumer prices. Thus in order to fight inflationary pressures central banks of LOEs that perceive themselves as SOEs could feel pressured to hike interest rates by more than necessary in order to bring inflation back to target.

5.3 Counterfactuals II and III: the role of the exchange rate

Since the euro area is not a small open economy, the effects of an appreciation of the Euro on the economy are twofold. Firstly, an appreciation of the Euro makes oil, which is denominated in Dollar cheaper in the euro area, if the cheaper prices are passed on to the consumers. We denote this effect as the local price effect of the exchange rate as it affects local prices in the euro area. These cheaper imports in turn, secondly, can translate into an increase in domestic demand for energy pushing up global prices and, in turn, local prices as well. This effect we denote as the global price effect of the exchange rate as it works via the global energy price.

Figure 4: Counterfactual I: the euro area as a SOE

Notes: Red lines refer to the MRE counterfactual, green lines to the structural scenario analysis counterfactuals. The second row shows the counterfactual using all shocks (SSA), the last row the counterfactual with the identified oil supply news shock (SSC). Notes: Impulse response functions to a one standard deviation monetary policy shock. Point-wise posterior means along with 68% and 90% point-wise probability bands. Horizon in months.

Taken together, both price effects render the impact that an exchange rate appreciation has on the local price is unclear a priori. In particular, an exchange rate appreciation could lower the local energy price if the exchange rate induced fall in local prices is larger than the demand induced rise in global prices. Or in other words: If the “local price effect of the exchange rate” dominates the “global price effect”, local energy prices will fall and vice versa.

In this section we again employ SVAR counterfactuals in order to first test which of the two price effects dominates the adjustment of local prices and second assess if the weaker effect is actually active after all. Because the debate if energy prices are only invoiced in dollars — which is akin to a Producer Currency Pricing (PCP) assumption— or even priced and sticky in dollars —which corresponds to the Dominant Currency Pricing (DCP) assumption— is not yet settled, we first focus on the Euro Area as the case is simpler (see Georgiadis and Schumann, 2021 for a discussion). In particular, as long as the appreciation of the Euro vis-a-vis the dollar translates into an appreciation of the Euro vis-a-vis the currency of energy exporters, the implications of PCP and DCP are identical for the local energy price of the euro area. For both paradigms an appreciation of the Euro should ceteris paribus lead to a fall in the local energy import price index of the EA. In the US case its more complicated because if energy prices would not only be invoiced but priced in dollars there would hardly be any pass-through of a dollar appreciation to US energy import prices.

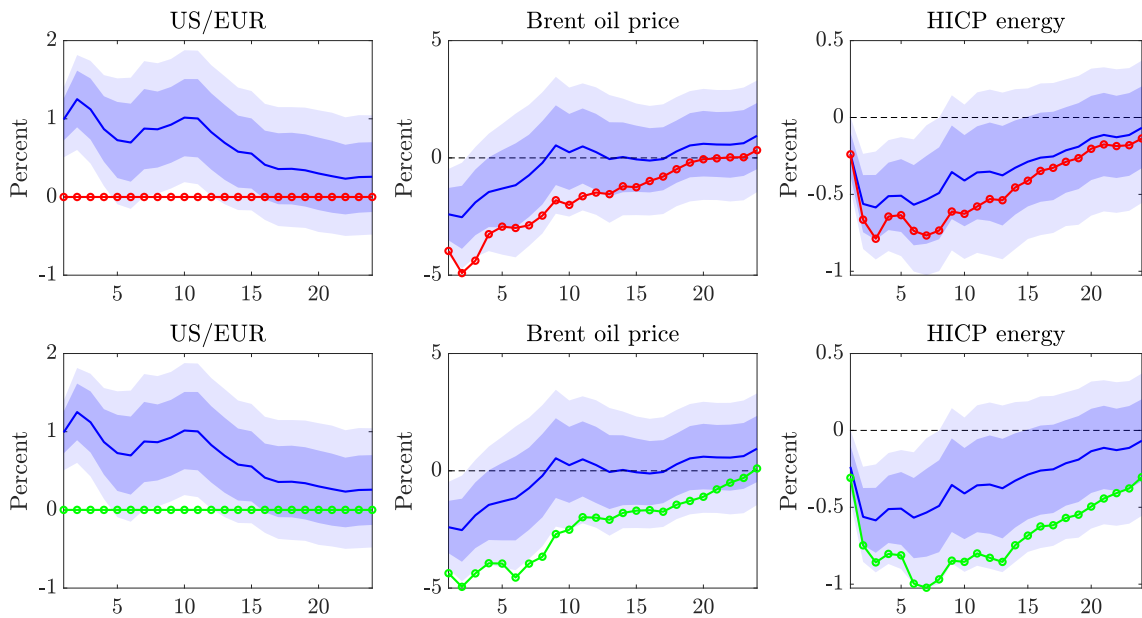

Figure 5 shows the results from our counterfactual exercise where we simulate (by means of SSA and MRE) a monetary policy shock that does not appreciate the exchange rate.¹²

The absence of the appreciation of the Euro implies that the our proxy for the global energy price —the Brent oil price measured in dollars— would fall much more. This is indicative evidence that the euro area demand for energy goods is indeed price elastic and, again, that the energy demand from the euro area influences global energy prices. In our model from Section 2 this translates into $\alpha_2 > 0$ and $\alpha_4 > 0$ respectively.

At the same time the local energy price as measured by the HICP energy index also falls in the counterfactual without the appreciation. At first sight this may seem contradicting as an appreciation of the exchange rate is usually believed to lower energy import prices. As such in a scenario where an appreciation is absent, energy import prices should rise. But, this is partial equilibrium intuition is reflected in Equation 4 it does not have to be an equilibrium outcome due to the “global price effect of the exchange rate”. In our counterfactual scenario the absence of the 1% appreciation of the Euro from the baseline scenario coincides with a fall of the global energy price as measured by the oil price in dollars by approximately 2%. Thus using the simple energy import price index of Equation 4 and evaluating the equation after all forces played out in general equilibrium, one concludes that the local energy price does not need to rise in a scenario where the appreciation is absent. In fact our counterfactual

¹²As we do not have a proxy variable to cleanly identify an exchange rate shock, we do not compute the SSC counterfactual for this exercise.

Figure 5: The role of the Euro appreciation

Note: Red lines refer to the MRE counterfactual, green lines correspond to the SSA counterfactual. Impulse response functions to a one standard deviation monetary policy shock. Point-wise posterior means along with 68% and 90% point-wise probability bands. Horizon in months.

scenarios indicate that it even falls. This leads us to conclude that in equilibrium the “global price effect of the exchange rate” overcompensates the “local price effect of the exchange rate” for the EA.

However, it is important to point out that our counterfactual scenario in Figure 5 does not indicate that there is no “local price effect of the exchange rate” i.e. no exchange rate pass-through in the Euro Area. In fact if that would be the case, the ECB could not even trigger a “global price effect” by manipulating the exchange rate. In order to test for the existence of a “local price effect” and gauge its importance we simulate a scenario where we force the counterfactual response of the Brent oil price to be the same as in the baseline and at the same time impose that the EA monetary policy does not appreciate the exchange rate. This counterfactual scenario allows us to analyze the effects of the exchange rate on the local energy price as measured by the HICP while shutting off its effect on the global energy price as proxied by the Brent oil price in dollars. The results from this exercise are shown in Figure 6 and indicate that there indeed exists a “local price of the exchange rate”. In particular, a monetary policy shock that has the same effects on the Brent oil price but does not appreciate the Euro vis-a-vis the dollar, causes the HICP energy index to *rise* relative to the baseline. This is in line with the partial equilibrium exchange rate pass-through intuition of Equation 4.

Figure 6: The local price effect of the exchange rate

Note: Impulse response functions to a one standard deviation monetary policy shock. Point-wise posterior means along with 68% and 90% point-wise probability bands. Red lines refer to the MRE counterfactual. Notice that the red dotted line lies by assumption exactly above the original blue impulse response for the Brent oil price.

6 Conclusion

In conclusion, our study contributes to the ongoing debate about the effectiveness of monetary policy in addressing inflation when it is driven by energy prices. Our results provide evidence that not only can the ECB fight inflation caused by high energy prices, but that energy prices, similar to the US, play an important role in the transmission of monetary policy in general. We refer to as the energy-price channel of monetary policy. For the euro area and the US this channel operates through changes of energy demand and a subsequent change in global energy prices, which then affect the overall inflation rate.

As oil is traded in Dollar, monetary policy in the euro area has two additional effects. Our analysis shows that while an appreciation of the Euro vis-a-vis the Dollar leads to lower local prices in the euro area, the stimulated demand for oil in the euro area pushes up global oil prices. We denote the latter effect the global price effect of the exchange rate and the former the local price effect of the exchange rate. Although there is a local price effect of the

exchange rate present, it is dominated by the global price effect.

Our findings have important implications for policymakers, especially at the ECB, who must take into account the complex interactions between monetary policy, energy prices, and the broader economy. Future research has to address the trade-offs for monetary policy when raising rates to fight inflation.
